

**Lightwave Guide Cable and Process for Carrying an Optical Signal, especially with  
Respect to Multiple Waveguide Techniques**

**CROSS-REFERENCE TO RELATED APPLICATIONS**

[0001] This application claims the benefit of priority under 35 U.S.C. § 119 of German Patent Application No. 100 61 836.7 filed on December 12, 2000.

**FIELD OF THE INVENTION**

[0002] The invention relates to an optical-waveguide cable, in particular for transmitting optical signals according to wavelength division multiplex technology. The invention furthermore relates to a method for transmitting optical signals in which such an optical-waveguide cable is employed.

[0003] Optical waveguides are increasingly being employed for data transmission. The optical waveguides, generally comprising glass fibre or plastic, are largely insensitive to electromagnetic interference and, moreover, are distinguished by very high transmission rates of up to a number of gbit/s. An optical waveguide is constructed from a thin cylindrical fibre made of a highly transparent, dielectric material, such as, for instance, doped quartz glass (SiO<sub>2</sub>), the so-called core glass, a cladding, the so-called cladding glass, surrounding the latter, and a generally single- or two-layer coating, the so-called primary coating, affording protection against mechanical influences. An optical-waveguide cable is composed of one or more optical waveguides which are encapsulated by a common cable sheath usually made of plastic, the so-called secondary coating, which additionally protects the optical waveguides against mechanical, thermal and chemical influences during laying and operation.

[0004] The data, generally present as electrical signal, are converted into an optical signal, that is to say a light beam having a specific wavelength, for transmission by means of an optical waveguide by an optical transmitter, for instance a laser diode. The light beam which is thus modulated with the data to be transmitted takes its course through the optical waveguide by undergoing total reflection at the boundary layer between core glass and cladding glass if the light is coupled into the optical waveguide below a specific angle, the angle of acceptance. The light beam also follows curves of the optical waveguide in this way.

The reason for this is that the core glass and the cladding glass are produced from materials which have different optical densities. After the optical signal has been transmitted through the optical waveguide, it is converted into an electrical signal again for further processing.

**[0005]** The transmission of the optical signal by means of an optical waveguide is based on amplitude, frequency or phase modulation of a light beam having a specific wavelength. In order to better utilize the transmission capacity of an optical waveguide, so-called wavelength division multiplex technology (WDM) is employed, in which different wavelengths are modulated, in other words different wavelengths are utilized for parallel transmission of a plurality of signals. An optical coupling element, the so-called wavelength division multiplexer, concentrates the different wavelengths into a wavelength division multiplex signal, which is then transmitted via the optical waveguide to the reception location, where it is split into the individual optical signals again by means of a wavelength division demultiplexer, for example a filter. Wavelength division multiplex technology is suitable for both unidirectional and bidirectional operation and usually utilizes wavelengths in optical windows at 850 nm, 1300 nm and 1550 nm.

**[0006]** Optical waveguides can be subdivided into monomode fibres (single-mode fibres) and multimode fibres, depending on the type of guidance of a light beam in the core glass. In the case of monomode fibres, the diameter of the core glass is of the order of magnitude of the wavelength of the light, so that only a single mode, the so-called fundamental mode, can propagate in the core glass. However, the mode also radiates beyond the core glass into the cladding glass. Therefore, the mode field diameter serves for indicating the light distribution of a mode, the said mode field diameter specifying the level at which the field amplitude of the light beam has fallen to  $1/e$  (approximately 37%) of its maximum value.

**[0007]** In the case of multimode fibres, by contrast, a plurality of discrete light waves, the modes differing primarily in terms of the field distribution and the propagation speed, contribute to the signal transmission. Depending on the type of configuration of the refractive index of the core glass, the multimode fibres can be subdivided into stepped-index fibres, in which the core glass and cladding glass have a constant refractive index, and graded-index fibres, in which the refractive index of the core glass decreases towards the outside. In the case of the stepped-index fibres, the light does not propagate parallel in the axial direction of

the optical waveguide, but rather is reflected between the core glass and cladding glass. The consequence of this is that a zigzag movement is produced and the individual modes cover different path lengths. These propagation time differences of the modes result in a widening of the light pulse, the so-called mode dispersion, which, usually together with chromatic dispersion, restricts the bandwidth of the optical waveguide. In order to avoid this, a defined profile of the refractive index in the core glass is provided in the case of graded-index fibres, with the consequence that the light is diffracted in the core glass. In this way, instead of a zigzag course, the light propagating in the core glass exhibits a wavy movement, in the case of which longer path lengths are compensated by a higher propagation speed.

**[0008]** In addition to the bandwidth influenced by the dispersion, the transmission capacity of an optical waveguide is principally characterized by the wavelength-dependent attenuation, that is to say the energy loss of the light beam in the course of a transmission path on account of scattering and absorption. Therefore, in the case of long transmission paths, amplifiers, such as for instance fibre-optic amplifiers, or regenerative repeaters are often used at specific intervals.

**[0009]** In order to achieve a high transmission range, it is advantageous, moreover, for the optical signal to be coupled into the optical waveguide with high power. However, the power which can be fed into an optical waveguide is limited by the occurrence of non-linearities, such as for instance so-called four-wave mixing. Although the upper power limit, characterized by the occurrence of these non-linear disturbances, can be increased by reducing the power density of the optical waveguide, for instance by means of a larger diameter of the core glass, and the provision of dispersion avoiding accumulation of the non-linear disturbances in the transmission band utilized, this increase is restricted by the fact that an excessively high dispersion brings about a linear expansion of the signals that are usually to be transmitted at a bit rate of 10 gbit/s per wavelength over a transmission path having a length of 60 to 80 km.

**[0010]** In the prior art, therefore, it is known to use fibres standardized according to ITU G 655, so-called "Non-Zero-Dispersion-Shifted fibres" (NZDS fibre), which, on account of their special configuration, have a dispersion of 2 ps/(nm·km) to 5 ps/(nm·km) in a transmission band with wavelengths around 1550 nm. What is disadvantageous in this case is

an increased attenuation of 0.23 dB/km, for example, compared with more or less conventional monomode fibres, which generally have an attenuation of approximately 0.20 dB/km. The paper by Ten et al.: Viable dispersion management scheme with standard and NZDSF fibers for 10 Gb/s wdm systems, ECOC 20 to 24 September 1998, Madrid, furthermore discloses arranging sections with fibres of positive and negative dispersion alternately one after the other, in order thus to obtain on average the desired dispersion. However, the provision of an optical-waveguide cable configured in this way is associated with a comparatively high outlay and is unsatisfactory from an economic standpoint.

### SUMMARY OF THE INVENTION

**[0011]** The invention is based on the object of providing an optical-waveguide cable with which dispersion that avoids non-linearities can be obtained in a simple manner in conjunction with a relatively low attenuation. Furthermore, the intention is to provide a method for transmitting optical signals in which such an optical-waveguide cable is employed.

**[0012]** What is proposed for achieving this object is an optical-waveguide cable, in particular for transmitting optical signals according to wavelength division multiplex technology, having at least one first section, which has fibres of a first type, and at least one second section, which has fibres of a second type, the fibres of the first type being connected to the fibres of the second type at at least one transition point between the first and second sections, and the fibres of the first type having a larger mode field diameter and a higher dispersion than the fibres of the second type.

**[0013]** An optical-waveguide cable designed in this way adopts the insight that undesirable non-linearities occur predominantly in a region of an optical waveguide which follows the transmitter or amplifier that feeds in the optical signal with high power. The reason for this is that a power loss occurs on account of the attenuation that unavoidably occurs in an optical waveguide, which power loss, after a certain transmission path, reduces the power of the signal fed in in such a way that the occurrence of non-linearities becomes negligible. Thus, for instance in the case of a relatively low attenuation of an optical waveguide of only 0.2 dB/km, an attenuation of, in total, 3 dB to 6 dB already results after 15 to 30 km, and significantly reduces the power of the signal fed in.

**[0014]** In the case of the optical-waveguide cable according to the invention, the first section having fibres of a first type with a comparatively large mode field diameter and a relatively high dispersion provides a high-level fibre which prevents the occurrence of non-linearities in the region following a transmitter or amplifier, which region is characterized by a still comparatively high power of the signal fed in. By contrast, the second section of the fibres - designed as low-level fibre - of a second type with a smaller, that is to say normal, mode field diameter and a smaller dispersion makes it possible for there to be a dispersion that is favorable with regard to a transmission of high bit rates starting from that point on the transmission path at which the non-linearities are negligible.

**[0015]** It is particularly advantageous to arrange the second section between two first sections. This is because a symmetrical arrangement of the form "high-level fibre/low-level fibre/high-level fibre" can be achieved in this way, which allows a high-power optical signal to be fed in from both ends of the optical-waveguide cable and is thus suitable for bidirectional operation. Thus, in contrast to the known embodiments, the optical-waveguide cable according to the invention is composed of only two strung-together sections in the case of unidirectional operation and only three strung-together sections in the case of bidirectional operation and is therefore comparatively inexpensive to produce.

**[0016]** With regard to the customary transmission methods, it is expedient if the fibres of the first type, which are designed as high-level fibre, have a mode field diameter of more than 8  $\mu\text{m}$  at a wavelength of 1550 nm and the fibres of the second type, which are designed as low-level fibre, have a mode field diameter of more than 6  $\mu\text{m}$  at a wavelength of 1550 nm. In order to avoid splice losses when connecting the fibres of the first type to the fibres of the second type at the transition point between the first and second sections, it has furthermore proved to be expedient if the mode field diameter of the fibres of the second type is less than 3  $\mu\text{m}$  smaller than the mode field diameter of the fibres of the first type.

**[0017]** Moreover, it is advantageous with regard to a practical configuration if the dispersion of the fibres of the first type, which are designed as high-level fibre, is between 12 ps/(nm·km) and 22 ps/(nm·km) in a transmission band of 1525 nm to 1625 nm and the dispersion of the fibres of the second type, which are designed as low-level fibre, is between

0 ps/(nm·km) and 12 ps/(nm·km) in a transmission band of 1525 nm to 1625 nm. It is advantageous, moreover, to provide a transition piece at the transition point between the fibres of the first type and the fibres of the second type, which transition piece gradually reduces the diameter of the core glass of the high-level fibres over a defined length of the optical-waveguide cable to the diameter of the core glass of the low-level fibres. Such a transition piece, which generally tapers conically in the direction of the smaller diameter, can be realized for example by a fusion splice, in which a gradual transition to the core diameter of the low-level fibre is achieved by pulling the end of the high-level fibre over a distance of generally more than 100 wavelengths.

**[0018]** In an advantageous development of the optical-waveguide cable according to the invention, the first and/or the second section are/is provided both with fibres of the first type and with fibres of the second type, in order to ensure a cable structure that is uniform and thus contributes to simple production. In this case, the fibres of the first type and the fibres of the second type are advantageously arranged in groups that are separated from one another, thereby making it possible to ensure unambiguous assignment and identification of high-level fibres and low-level fibres. For this purpose it is advantageous, moreover, if the fibres of the first type and the fibres of the second type are in each case designed as fibre bundles, fibre ribbons or bundle cores.

**[0019]** Moreover, for achieving the above object, a method for transmitting optical signals in particular according to wavelength division multiplex technology, is specified, in which the optical signals to be transmitted are coupled into fibres of a first type, which are provided in a first section of an optical-waveguide cable, and, after a specific transmission path, are conducted into fibres of a second type, which are provided in a second section of the optical-waveguide cable, the fibres of the first type being connected to the fibres of the second type at at least one transition point between the first and second sections, and the fibres of the first type having a larger mode field diameter and a higher dispersion than the fibres of the second type.

**[0020]** Such a method makes use of the above-described advantages of the optical-waveguide cable according to the invention in order to achieve dispersion that avoids non-

linearities in a simple manner in conjunction with a relatively low attenuation of the optical-waveguide cable.

**[0021]** In a development of this method, it is furthermore proposed that after a specific transmission path through the fibres of the second type of the second section, the optical signals to be transmitted are conducted into fibres of the first type of a further first section, in order to enable bidirectional operation. Finally, it is proposed that the individual optical waveguides of the optical-waveguide cable be coupled by a so-called pigtail, a connecting fibre prefabricated with a connector, or a patch cable, a fully fabricated connecting cable with connector types configured for simplex or duplex technology, to a transmitter, a receiver or an amplifier provided between the transmitter and receiver. This affords the advantage that an optical-waveguide cable with first and second sections which have both fibres of the first type and fibres of the second type can also be connected with a comparatively low outlay.

#### **BRIEF DESCRIPTION OF THE DRAWINGS**

**[0022]** Details and further advantages of the subject-matter of the present invention emerge from the following description of two preferred exemplary embodiments. In the associated drawing, in detail:

**[0023]** Figure 1a illustrates a diagrammatic representation of a transmission path formed by a conventional optical-waveguide cable with, for example, monomode or NZDS fibres;

**[0024]** Figure 1b illustrates a diagrammatic representation of a transmission path formed by a conventional optical-waveguide cable with alternate sections of fibres of positive and negative dispersion;

**[0025]** Figure 2a illustrates a diagrammatic representation of a transmission path formed by an optical-waveguide cable of a first embodiment of the present invention;

**[0026]** Figure 2b illustrates a diagrammatic representation of a transmission path formed by an optical-waveguide cable of a second embodiment of the present invention;

**[0027]** Figure 2c illustrates a representation in accordance with Figure 2b which shows a transition point between the sections of the optical-waveguide cable of the second embodiment in more detail;

**[0028]** Figure 3a illustrates a cross section through an optical-waveguide cable according to the invention with fibres grouped into bundle cores, and

**[0029]** Figure 3b shows a cross section through an optical-waveguide cable according to the invention with fibres grouped into fibre ribbons.

### **DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS**

**[0030]** A conventional optical-waveguide cable is employed for the transmission path composed of sections c which is illustrated in Figure 1a, which cable in each case comprises fibres of a single type, for example monomode fibres or NZDS fibres in the sections c. Primarily in the case of an optical signal which is coupled in with high power, such a transmission path is affected by the disadvantages described in the introduction, such as for instance the occurrence of non-linearities. Although the transmission path which is represented in Figure 1b is formed from an optical-waveguide cable in which sections d1 having fibres of positive dispersion and sections d2 having fibres of negative dispersion alternate with one another, in order thus to obtain on average a dispersion that avoids non-linearities, such cable management is nonetheless characterized by complicated and economically unsatisfactory production of the optical-waveguide cable.

**[0031]** In contrast to this, the transmission path which is shown in Figure 2a comprises an optical-waveguide cable which is composed of a first section a and a second section b. The section a has fibres of a first type H, which are formed with a comparatively large mode field diameter and a comparatively high dispersion as high-level fibres. By contrast, the section b has fibres of a second type N, which, provided with a smaller mode field diameter and smaller dispersion, are formed as low-level fibres. At the transition point U between the section a and the section b, the fibres of the first type H are connected to the fibres of the second type N by a fusion splice. The fusion splice ensures a low splice loss with values of between 0.03 dB and 0.3 dB, for example.

**[0032]** The fibres of the first type H are designed in such a way that they have a mode field diameter of more than  $8\text{ }\mu\text{m}$  at a wavelength of  $1550\text{ nm}$  and the dispersion is between  $12\text{ ps}/(\text{nm}\cdot\text{km})$  and  $22\text{ ps}/(\text{nm}\cdot\text{km})$  in the transmission band of from  $1525\text{ nm}$  to  $1625\text{ nm}$ . In comparison with this, the fibres of the second type N have a mode field diameter of more than  $6\text{ }\mu\text{m}$  at a wavelength of  $1550\text{ nm}$ , the difference between the mode field diameter of the fibres of the first type H and the fibres of the second type N being less than  $3\text{ }\mu\text{m}$ . The fibres of the second type N are furthermore configured in such a way that the dispersion has a magnitude of between  $0\text{ ps}/(\text{nm}\cdot\text{km})$  and  $12\text{ ps}/(\text{nm}\cdot\text{km})$  in the transmission band of from  $1525\text{ nm}$  to  $1625\text{ nm}$ .

**[0033]** If optical signals are coupled into the fibres H of the section a with high power by a transmitter S or an amplifier V, then the occurrence of non-linearities is effectively prevented on account of the comparatively large mode field diameter and the comparatively high dispersion of the fibres H designed as high-level fibres. On account of the unavoidable attenuation, however, the energy, that is to say the light power, of the optical signal is reduced in the course of the section a. After 10 to 20 km, the light power of the optical signal has decayed to such an extent that the probability of the occurrence of non-linearities becomes negligibly low. The optical signals are then conducted at the transition point U into the fibres N - designed as low-level fibres - of the generally significantly longer section b which reaches as far as the receiver E or as far as an intermediate repeater V. The smaller dispersion and the smaller mode field diameter of the fibres N which are then optimized for transmission at a specific bit rate result in a high degree of utilization of the bandwidth of the optical-waveguide cable.

**[0034]** The above-described arrangement of the optical-waveguide cable in accordance with Figure 2a is only suitable for unidirectional operation, however, since coupling optical signals with high power into the fibres N - designed as low-level fibres - at the end of the section b does not lead to the advantages described above. An arrangement which is suitable for bi-directional operation is shown in Figure 2b. In this embodiment of an optical-waveguide cable, a second section b is arranged between two first sections a, so that optical signals can be coupled in with high power from both ends of the optical-waveguide cable, without running the risk of non-linear disturbances occurring.

**[0035]** Figure 2c represents the transition point U between the section a and the section b in greater detail. A transition piece T can be discerned, which is provided between the fibres of the first type H and the fibres of the second type N. The transition piece T gradually reduces the diameter of the core glass of the fibres of the first type H over a length corresponding to the respective application, which length generally amounts to at least 100 wavelengths, to the core diameter of the fibres of the second type N. If, as already explained above, a fusion splice is used to weld the fibres H designed as high-level fibres to the fibres N designed as low-level fibres N, then a transition piece T which tapers conically in the direction of the smaller diameter can be formed by the end of the fibres H designed as high-level fibre being pulled lengthwise and thereby narrowed. The light beams within the core glass traverse a funnel-shaped bottleneck in this way.

**[0036]** Figures 3a and 3b reveal that the optical-waveguide cable used in the arrangements in accordance with Figures 2a to 2c can be provided both with fibres of the first type H and with fibres of the second type N in the sections a and b. Such a uniform cable structure ensures simple and inexpensive production. In order, moreover, to ensure unambiguous assignment and identification of fibres H designed as high-level fibre and fibres N designed as low-level fibres, which contributes to practical assembly, the fibres H and the fibres N are arranged in groups that are separated from one another. Figure 3a shows a grouping in which the fibres H, N designed as bundle cores are arranged around a cable core K. The cable core K, for instance a rod of glass-fibre reinforced plastic, serves for thermal and mechanical stabilization of the optical-waveguide cable. Such stranding affords the advantage, moreover, that an extension of the individual fibres H, N becomes largely independent relative to the extension of the entire optical-waveguide cable. By contrast, Figure 3b shows a grouping in which the fibres of the first type H and the fibres of the second type N are in each case designed as fibre ribbons.

**[0037]** The optical-waveguide cable described above makes it possible to ensure a dispersion that avoids non-linearities in a simple manner in conjunction with a relatively low attenuation overall. The reason for this is primarily the provision of at least two sections a, b provided with high-level fibres H and low-level fibres N, respectively. In this case, it is also possible for the optical-waveguide cable to have a structure in which fibres H designed as high-level fibres and fibres N designed as low-level fibres are simultaneously present in the sections a,

b. Depending on the application, such mixed sections can also be combined with uniform sections of a single fibre type. Last but not least, practical cabling is taken into account by the grouping of the fibres N, H in mixed sections.

**List of reference symbols**

a	First section
b	Second section
c	Section comprising monomode fibres or NZDS fibres
d1	Section comprising fibres with positive dispersion
d2	Section comprising fibres with negative dispersion
